Abstract

As more productivity data become available, it is possible to examine the effects of people and practices on productivity. Arguably, the most important relationship in the firm is between worker and supervisor. The supervisor hires and fires, assigns work, instructs, motivates and rewards workers. Models of incentives and productivity build at least some subset of these functions in explicitly, but because of lack of data, little work exists that demonstrates the importance of bosses and the channels through which the productivity enhancing effects operate. Using a unique company based data set, supervisor effects are estimated and found to be large for technology-based services workers. The three most important findings are: The only “peer” that matters is the boss. In this environment peers have little or no effect on output, but bosses affect workers significantly. Second, there is substantial variation in boss quality, measured by their effect on worker productivity. Replacing a boss who is in the lower 10% of boss quality with one who is in the upper 10% of boss quality increases a team’s total output by about the same amount as would adding one worker to a nine member team. Third, the marginal product of a boss is about twice that of a worker, commensurate with the ratio of their wages. Additionally, good bosses should be sorted to the star workers because although good bosses increase the productivity of both good and bad workers, they increase it by more for the firm’s top performers.

Workers depend on their bosses in many ways. First, the hiring decision is generally made with input from a worker's superiors, sometimes direct, sometimes more removed. Second, the supervisor is likely to be important in motivating a worker, which in turn affects raises, promotions and other benefits. In extreme cases, supervisors discipline and terminate workers. Third, supervisors assign tasks to workers and tell them what they must do and may not do on the job. Fourth, the supervisor acts as mentor or coach, teaching his subordinates the techniques that will enhance their productivity.

Despite the clear and important role that supervisors play, the economics literature has been silent on the effects that bosses actually have on affecting worker productivity.¹ Even more to the point, the literature has not been able to speak to the importance of the various mechanisms through which boss effects might operate. Most of this is a data issue, but some of it reflects the fact that the literature has modeled the relationship between boss and worker at an abstract level and has not pushed beyond to ask about what is likely to be the most important relationship in the workplace.

The neglect is even more striking when contrasted with the interest in peer effects. There is a large literature, both theoretical and more recently empirical, that has focused on the effects of workers on their peers and team members.² Peer effects may be important, but except in a few

¹Some early exceptions are Herbert Simon on firm size and compensation (1957) and Rosen on the span of managerial control (1982).

²For theory, see Kandel and Lazear (1992). For empirical examples, see Mas and Moretti (2009), and Falk and Ichino (2006). For work on teams and complementarities, see

industries, like academia, where the structure is very flat and workers have much authority over what they do, the relationship with one's boss is likely to be as or more important than that to any other worker. At a minimum, this remains an open question and one that should be investigated.

By using data from a large service oriented company, it is possible to examine the effects of bosses on their workers' productivity and to compare them to individual and peer effects. The primary findings are:

1. Bosses are important and vary in productivity. Replacing a boss who is in the lower 10% of boss quality with one who is in the upper 10% of boss quality increases a team's total output by about the same amount as would adding one worker to a nine member team.
2. The marginal product of a boss is about twice as large as the marginal product of a typical worker. The ratio is consistent with differences in compensation levels.
3. Bosses are the only "peer" that matters. Peer effects are small or zero, whereas boss effects are substantial.
4. Good bosses increase the productivity of many different types of workers. Bosses who are good for old workers are also good for new workers.
5. The difference between the effect of good and bad bosses on high quality workers is greater than that on lower quality workers, which suggests that to the

Ichniowski and Shaw (2003).

extent that the same boss is good for both, the assignment of the good boss should be made to the higher quality worker. Comparative advantage is key. Allocating bosses appropriately can raise firm productivity.

I. Theoretical Framework

Workers and bosses together produce output.

A. The Output of Workers and Bosses

An individual's output, q , depends on human capital, H , which reflects both innate ability and previously learned skills, and on effort, E . A natural specification is multiplicative: harder work results in greater returns to human capital

$$(1) \quad q = H * E.$$

For example, one measure of effort is time worked. H is normalized such that the average worker has $H=1$. H scales hours appropriately to turn effort, here hours, into units of output. A "unit" of output is then defined as the amount of output that an average worker produces in one period.

For now, let us focus on the motivating and teaching roles of supervisors and ignore task assignment, hiring, firing and other aspects of the supervisor job. It is necessary to define boss effects before they can be discussed. Because every worker has a boss, at least at some level, the boss effect cannot be the difference between having a boss and not having one. Instead, think of the boss effect as the importance of different quality bosses on the output of their subordinates. Without loss of generality, define an index S_i , $i=t,m$ for teaching and motivation. The best boss is defined as the boss who has the largest positive effect on subordinates' output. The worst boss

is defined as the boss who has the smallest positive or possibly even most negative effect on worker output.

Then the boss effect is defined from (1) for teaching and motivating as

$$(2) \quad \frac{\partial q}{\partial S_i} = E \frac{\partial H}{\partial S_i} + H \frac{\partial E}{\partial S_i} \quad i = t, m$$

The first term reflects the effect of having a better boss in either the teaching (subscript $i=t$) or the motivating dimensions (subscript $i=m$), on a worker's output through the human capital (H) channel. Higher quality bosses impart more knowledge on their subordinates and the first term refers to that effect. The second term reflects the effect of having a better boss on a worker's output through the effort (E) channel. The indexes S_t and S_m refer to the amount of quality adjusted time that a supervisor places on H and on E, respectively. It seems reasonable that the effect of S_t , supervisor teaching time, would operate primarily through H and the effect of S_m , supervisor motivating time, would operate primarily through E, but nothing in the specification requires this.

One can think of S_t and S_m as partly reflecting endowments to supervisors of teaching and motivating skills and in partly reflecting choice over investment as time allocation between motivating and teaching skills or activity.

There are a number of different supervision processes that have economic interpretations. One possibility is that S_t is exactly proportionate to S_m and that nothing else matters. There is fundamentally only one kind of supervisory ability, S, and motivating ability and teaching ability are proportionate to it. Then $S_m = \lambda_m S$, $S_t = \lambda_t S$ so $S_t = (\lambda_t/\lambda_m)S_m$. In this case, the best

motivators are also the best teachers. A regression of S_t on S_m would yield an intercept of zero and an R^2 of one.

Another possibility is that all bosses have an identical fixed amount of quality-adjusted supervisor time, and that

$$\text{Fixed time} = S_m + S_t$$

so that S_t equals a constant minus S_m , where the time spent on each of motivating and teaching is a choice variable. Those supervisors who, for whatever reason, spend more time motivating spend correspondingly less time teaching. A regression of S_t on S_m would yield a coefficient of negative one on S_m , again with an R^2 of one.

Another view is that of S_t and S_m are endowed in bosses and not subject to choice at all. Whether S_t and S_m are observed to be positively or negatively correlated in the population of bosses would depend on the joint density of S_m and S_t that characterizes the population. One possibility is that nature endows skills in ways that result in positive observed correlations. Those who are best able to teach are also able to be efficient motivators. An alternative is that S_t and S_m are negatively correlated in the population. Drill sergeants may be good at getting subordinates to show up for work, but may not be great psychotherapists or nurturing teachers so that those who are endowed with high S_m skills are also endowed with poor S_t skills.

A general formulation allows S_{t^*} and S_{m^*} to be random variables that are endowed, but allows choice on the part of the supervisor to move some quality-adjusted time from teaching to motivating. For example, one could write

$$S_t = S_{t^*} + \lambda(S_{m^*} - S_m)$$

where $\lambda \leq 1$. The supervisor can turn some motivating into teaching and vice versa, perhaps at a

cost.

The question is an empirical one and cannot be settled a priori. If a positive correlation is observed, then it is necessarily the case that individuals differ in their overall endowments (or acquired levels) of quality adjusted time or of the specific teaching and motivating skills. It is still possible that bosses have the ability to choose how much of their time to spend on motivating versus teaching, but in order to observe positive correlations across people in S_m and S_t , it is necessary that total quality-adjusted supervisory time varies.

Whether choice is involved remains crucial, but difficult to determine empirically. If there is room for choice, then the senior management can simply instruct supervisors to alter their time allocation in a direction that enhances supervisor productivity. If, on the other hand, little or no choice is involved and the observed S_t and S_m varies across people because of their endowments, then senior management's only tools for affecting the allocation between teaching and motivating is the recruitment of the supervisors with the best combination of talents and the firing of those with the worst.

This framework suggests the following empirical questions:

E1: Do bosses matter? Do they raise workers' output? If so, by how much? Specifically, if bosses do matter, then some combinations of bosses' levels of S_t and S_m must differ across bosses.

E2: Do bosses matter because they teach or because they motivate? Which dominates? Given equations (1) and (2), some assumptions must be made to distinguish between teaching and motivation.

E3: Is a good boss good at both teaching and motivating because these are endowed traits; or, are

teaching and motivating substitutes in the boss's allocation of time on the job?

B. Sorting Bosses to Workers

Sorting is key. Should good bosses be matched with good workers? Suppose good workers are defined as those who have higher levels of human capital, H . From (2), the boss effect depends on the effect of H on output:

$$\frac{\partial^2 q}{\partial S_i \partial H} = \frac{\partial E}{\partial H} \frac{\partial H}{\partial S_i} + E \frac{\partial^2 H}{\partial S_i \partial H} + H \frac{\partial^2 E}{\partial S_i \partial H} + \frac{\partial E}{\partial S_i}.$$

The sign is ambiguous. Because E is a choice variable for the worker and because there may be a relation of H to E , $\partial E/\partial H$ cannot be assumed to equal zero. All other terms are positive with the exception of $\partial^2 H/\partial S \partial H$ and $\partial^2 E/\partial S \partial H$, which cannot be signed a priori. If a good boss were more valuable to less able workers than to more able ones, then $\partial^2 H/\partial S \partial H$ would be negative. Similarly, if good motivating were more important for lazy workers than for energetic ones, $\partial^2 E/\partial S \partial H$ would be negative. Sufficiently strong effects of either or both types could mean that it is better to sort good bosses with low ability workers. This is an empirical question, but one that can be resolved by the data used in the empirical section.

Thus, additional questions are:

E4: Do boss effects differ for star workers and laggard workers? A laggard may have more room for improvement; a star may be more receptive to improvement.

E5: Are there complementarities between bosses and workers? Does a good bosses produce more output when matched with star workers than when matched with laggard workers?

C. Workers are Additive; Bosses are Multiplicative

Why is a research scientist who has a great breakthrough so valuable to a firm? It is

because the innovation enhances the productivity of a large number of workers. The effect is multiplied by the number of workers that it affects.

The same is true of bosses. A good claims processor can process a larger number of claims than a poorer one, but the effects are limited to the claims that the worker processes himself. The quality of supervisor affects output primarily through the work of subordinates and an increase in supervisor quality is multiplied by the number of individuals who are touched by that supervisor. Thus, the effects are multiplicative for supervisors and additive for workers.

Formally, the total output of the firm, Q , is the sum of the individual worker's (excluding supervisor) outputs, q_i ,

$$(3) \quad Q = \sum_i q_i \\ = \sum_i q(x_i) + \alpha_i + \sum_j \delta_j D_{ij}$$

where x_i are observables that affect output (like tenure and time), α_i is worker i 's fixed effect, δ_j is boss j 's fixed effect and D_{ij} is a dummy equal to one if worker i is a subordinate of boss j . It follows from (3) that

$$\frac{\partial Q}{\partial \alpha_i} = 1 \\ \frac{\partial Q}{\partial \delta_j} = \sum D_{ij}$$

Thus, the effect of worker talent on output is just the effect itself, whereas the effect of the boss's talent on output is multiplied by the number of individuals that she supervises.

Peers could have the same multiplicative effect as bosses. If one peer influences all his team members, his effect is multiplicative in the same way as that of the boss.

E6: Are boss effects bigger than peer effects?

II. Data

The data contain four years of daily productivity transaction records between June 2006 and May 2010 from an extremely large services company. There are 23,878 unique workers and unique 1,940 bosses, for a total worker-day sample size of about 5.7 million observations. This company has multiple different service functions, but the data used come from one task classification where workers are involved in general customer transactions. This ensures that all workers in the sample perform approximately the same tasks. Because of confidentiality restrictions, most detail about the day-to-day tasks that workers perform must be suppressed. The data come from many sites, but number of sites is also suppressed for confidentiality reasons.

The jobs are labeled, “technology-based service” jobs or “TBS jobs.” Examples include insurance-claims processing, computer-based test grading, technical call centers, some retailing jobs such as cashiers, movie theater concession stand employees, in-house IT specialists, airline gate agents, technical repair workers, and a large number of other jobs.

Consider a detailed example of a TBS job: workers doing computer-based test grading. Most U.S. states expect students to take standardized tests, such as the “Star” tests in California. The students’ handwritten essays (from science to English) are scanned into a computer, and then the graders of these tests sit in large rooms, where they grade each essay on a computer. Their work is timed and checked for quality. They must be at their desk a certain percent of the day (defined as ‘uptime’ below), which is recorded. They have modest amounts of incentive pay. They are often given daily feedback on their performance, and they can see some measures

of the performance of other team members. Their bosses sit with them and teach and motivate the workers. While this may seem like an unusual example, we made a number of plant visits to companies like this, and all visits shared this typical scenario.

These are labeled TBS (technology-based service) jobs because the company uses some form of advanced IT system to record the beginning and ending time for each transaction, or to record the daily volume of transactions, for each worker. As described above, many production processes in services now fit this description. The technology that is used to measure performance may be a new computer-based monitoring system (as in the standardized test grading above), an ERP (Enterprise Resource Planning) system that records a worker's productivity each day (such as the number of windshield repair visits done by each Safelite worker (Lazear, 1999; Shaw and Lazear, 20xx)), cash registers that record each transaction under an employee ID number, call centers, or computer-monitored data entry. These TBS jobs are likely to be widespread and represent a major IT-based shift in computerization and worker productivity. While some of these jobs are outsourced to firms outside the U.S., many remain in the U.S., particularly when the customer interaction is face-to-face or the work is idiosyncratic and skilled (as in test grading).

In our data, the TBS workers are doing reasonably technical work, with a computer interface. New products or processes are introduced over time, and thus there is constant learning on the job. Bosses are constantly teaching.

The workers are working in areas, which are labeled "teams" herein. In this firm, the average daily team size is 9.04 workers, and each team is managed by one boss. The team is identified through the worker's link to a boss identification number; all workers with the same

boss that day are said to be part of the team. Workers switch bosses about four times a year.³ It is these switches to different bosses that permits us to estimate the effect of bosses on worker productivity.

There are two measures of output. One is productivity, which is output-per-hour, and as shown in Table 1, in these data each worker handles about 10.3 transactions per hour. The second measure is uptime. In any hour at work, workers miss some of the time for breaks, etc., leaving their work areas and thereby slowing the entire system. The mean uptime is 96.3%, and the standard deviation is a small 3.0%. See Table 1 footnotes for more details.

Most of the variation is in output-per-hour rather than in uptime. The standard deviation of output-per-hour is 30.8% of its mean; the standard deviation of uptime is 2.8% of its mean. Consequently, the initial discussion and results focus on variation in output-per-hour. Later, the analysis is done on uptime. Most of the workers' variation in performance operates through productivity rather than uptime. Temporal variation in the demand for a worker's services can be taken into account through the use of time dummies and by using the group mean output for other workers on any particular day (described below in footnote 7).

III. Empirical Results: Boss Effects and Peer Effects

A. Boss Effects

The most important finding is that bosses have large, varying and significant effects on worker productivity. Table 2 reports the basic regression results where output-per-hour is the dependent variable. The basic unit of observation is a worker-day so that each of the 5.7 million

³ The worker-boss pair is defined by the usual worker-boss pairing. If a boss were absent on any given day, the usual boss would be the one of record.

observations represents output for a given worker on a day on which he worked. The baseline productivity regression is

$$(4) \quad q_{ijt} = X_{it}\beta + \alpha_i + \delta_j + t + \varepsilon_{ijt}$$

Column 1 reports the R-squared from the most basic regression of output-per-hour on a fifth order polynomial of daily tenure and monthly time dummies while restricting $\alpha_i = \alpha$ for all i and $\delta_j = 0$. Not surprisingly, and consistent with prior work in other industries,⁴ the output is increasing and concave in tenure (results are shown in section IV.A. below).

The rest of Table 2 is of primary interest. In column 2, worker fixed effects are added to the basic regression. Worker fixed effects are clearly important. The R-squared rises from 0.059 to 0.237 with an $F(23877, 5729508)$ statistic of 55.5 (p-value = 0), rejecting the null hypothesis that the set of individual fixed effects are zero. The variation in fixed effects is large. A one-standard deviation increase in the worker fixed effects increases worker output-per-hour by 56%.⁵ Column 3 includes only boss fixed effects. Boss fixed effects also matter. The R-squared increases from 0.059 to 0.091 with an $F(1939, 579508)$ statistic of 103.4 (p-value = 0), rejecting the null hypothesis that the boss fixed effects are jointly zero. Although the importance of the boss effect is striking, because of potential non-random assignment of workers to bosses, little can be inferred about the importance of bosses without taking worker effects into account.

The more important results are in column 4, which includes both worker and boss effects. Here, worker fixed effects and boss fixed effects are estimated jointly with dummy variables

⁴See Lazear (2000), Shaw and Lazear (2008) for examples with productivity data.

⁵ It is well-known that there is significant variation in worker wages and that in panel data, the worker-specific fixed effects explain much of that variation. It is less well-known, primarily because of lack of data on individual worker productivity, that there is significant variation in worker productivity and that worker fixed effects explain much of the variation.

included so that $D_{ij} = 1$ if individual i has boss j as his supervisor on the day of the observation in question.⁶ With both fixed effects, the R-squared rises to 0.242. Worker fixed effects and boss fixed effects are each significant. The $F(23878, 5703638)$ statistic is 47.5 (p-value=0) on worker fixed effects and, for the boss effects, the $F(1940, 5703638)$ statistic is 20.3 (p-value = 0). While the levels of workers' productivity can be affected by demand conditions for their services, careful analysis of the robustness of the results suggests that the magnitudes revealed here are little changed with a range of controls for varying demand conditions.⁷

⁶ Boss and worker effects are both estimated from a full set of dummy variables using a sparse matrix implementation. Because of the large size of the matrix of regressors, a conjugate gradient algorithm is used to minimize the sum of squared residuals. Credible standard error estimates are only available using complicated re-sampling techniques because of the two-way structure of the panel, so inference instead relies on comparisons of restricted and unrestricted models: F-statistics are used to test for the introduction of alternative sets of fixed effects, which are the core theme of this paper. In addition, the fixed effects are identified within "connected groups" of workers and bosses. Over 99% of the workers and bosses in the data are connected in the same group. The estimated fixed effects are only identified up to normalizations, so the mean of the worker effects is set to zero and one boss effect is zero. For a precise statement of the identifying conditions, see Abowd, Creecy, and Kramarz (2002).

⁷Market conditions might affect output some, but this is really a question of how good the firm is at adjusting the number of employees so as to keep the transaction arrival rate, which will be referred to as demand, close to constant for any given worker. Because this firm adjusts the number of hours worked so as to ensure that workers have virtually no slack, there is relatively little variation in output that is caused by fluctuations in transaction arrival rates (demand shocks). Introducing daily time dummies as well as person and boss fixed effects leaves very little remaining variation; monthly time dummies are introduced and are significant. One method for assessing the robustness of these results with respect to demand shocks is contained in the Peer Effects regression in Table 3, column 1. Peer effects are introduced by adding a variable that is the mean contemporaneous (daily) output for all other team members excluding the worker. This mean value of daily team output will clearly pick up changes in daily demand, and therefore, it has a strong positive coefficient in the Table 3 results. However, the standard deviation of the estimated worker effects and boss effects falls only very modestly when this stringent control for demand is introduced.

Bosses affect all workers that they oversee, and each boss effect must be multiplied by the number of workers supervised by the boss to get the effect of the boss on overall productivity. The last few lines of Table 2 report the boss effects while assuming that each boss is assigned to an average size team.

Even among the selected sample of those who are promoted to boss, there is large variation in the effect of bosses on worker output. The variation in the effect of bosses on output is about two-thirds as great as the effect of individual variation in worker quality on total output. This is one of the most significant findings of the paper.⁸

It is not surprising that bosses differ in their quality and effect on output, but it is noteworthy that being assigned to one boss over another affects worker productivity by as much as individual worker variation does.

To get a sense of the magnitude of this effect, the standard deviation of boss effects is between 65% and 112% of the standard deviation of worker fixed effects, depending on the weighting. (The estimated boss effects can be weighted by worker-day or by boss, and the different results are described in the next sub-section B and the footnotes to Table 2.) Replacing a boss who is in the bottom 10% with one in the top 10% of quality is equivalent to gaining

⁸ There are three estimates of boss effects reported in the table: the weighted boss effects use the boss*agent day weights to give more weight to bosses who have greater presence in the data. The boss effects that are unweighted take an individual boss as the unit of observation. The unweighted boss effects likely reflect variation that mirrors the set of potential bosses. Because the set of bosses observed in the data is likely a selected sample, there is a plausible argument that the measure with more variation (unweighted) should be used. However, there is a tradeoff between precision of the estimated boss effects and sample selection—as a boss interacts with more workers for longer periods of time, the individual boss effect can be estimated more precisely. More will be said about this in section C below.

about 123% of a typical worker's output.⁹ Put differently, changing from a boss in the bottom 10% to one in the top 10% would be about as important as adding a full worker to the team that is supervised.

Finally, it is important to remember that the estimates of boss effects are lower bounds of the maximum boss effect because of the promotion rule. The worst conceivable boss is not likely to be in our sample of bosses.

B. The boss effects are identified

Holding constant the worker's quality, α_i , the boss effect δ_j , is identified by those workers who switch bosses. The boss effects in (4) are estimated off "changers." In order to estimate the effect of a boss on worker productivity, the same boss must work with different workers, whose abilities are known through the worker fixed effects. Logically, if a given worker switches from boss A to boss B and his productivity rises, then the change in productivity is attributed to the change in bosses. For any given boss, the boss effect is therefore estimated as the average over all workers' changes to that boss. More precisely, the boss effects are estimated within "groups" of connected workers in the graph-theoretic sense.¹⁰ If a separate group of bosses and workers is not connected, no worker or boss ever interacts with any other worker or boss in the non-connected group. Within each group, there must be one normalization of the boss effects and one normalization of the worker effects.

⁹ This is calculated as $6.42 - (-6.24) / \text{mean output}$, where 6.42 and -6.24 correspond to the top and bottom quintile of the unweighted boss effects.

¹⁰ "When a group of [workers] and [bosses] is connected, the group contains all the workers who ever worked for any of the bosses in the group and all the [bosses with] which any of the workers were ever [assigned]" (Abowd, Kramerz, and Woodcock, 2006).

To get a sense of what this means, suppose that there are two bosses interacting with several workers in a single connected group. Because both bosses and all workers are connected, this means that some workers switch bosses. The relative difference in the boss effect is just $\delta_2 - \delta_1$. Constraining $\delta_1=0$, δ_2 is estimated from the set of workers that switch bosses. Now suppose there is a third boss who is in the connected group. Being in the same connected group implies that at least some workers have been supervised by boss 3, and at least one of these workers has worked with another boss. In this case, δ_3 is identified from switches between boss 3 and boss 2 or boss 3 and boss 1 because δ_2 is already identified relative to δ_1 .

Stated more generally, within each connected group, $\delta_j = E(y \mid \text{Boss } j) - E(y \mid \text{Boss } 1)$ where δ_1 is normalized to equal 0 for the first boss within each group. Each boss effect captures the bosses' change in productivity relative to the excluded boss. What conditions are necessary such that $\delta_j = E(y \mid \text{Boss } j) - E(y \mid \text{Boss } 1)$? To estimate this average treatment effect, of changes in boss quality on worker productivity, either there is random sorting between bosses and workers after accounting for the worker's fixed effect and X , or the boss treatment effects must be homogeneous across workers. That is $\delta_j = E(y \mid \text{Boss } j, \text{worker } i) - E(y \mid \text{Boss } 1, \text{worker } i) = E(y \mid \text{Boss } j, \text{worker } k) - E(y \mid \text{Boss } 1, \text{worker } k)$ for all workers i and k . Sorting of workers to bosses and heterogeneity in the treatment effects are addressed in detail below in section VI.

How much data is there to estimate the boss effects within each connected group? The dataset is the population of workers in the firm from 2006 to 2010. For each worker, there is an average of 240 days of daily productivity data (or about a calendar year of data). Each worker changes bosses about 4 times during this interval. Therefore, when the boss is the unit of analysis, his team members have, on average, touched 4.7 other bosses. Given the average

number of workers per boss, the number of worker changers per boss is 49 (or 80 if weighted by the number of observations per boss). These are sizable numbers. As a result, 99.99% of the daily data is in the largest connected group, with only 560 of the 5.7 million observations and 11 of the 1,940 bosses outside of the largest group.

C. Are the results sensitive to the number of observations per boss?

Some bosses are long-lived in the data set; others are short-lived and thus have few workers per boss identifying their boss effect. The short-lived bosses introduce noise into the estimation of the boss effects, but the conclusion that bosses have large and varying effects is unchanged when we take this noise into account and attempt to correct for it.

In Table 2, the boss effects are reported in three ways, corresponding to the three rows under the heading “Standard Deviation of Boss Effects.” All estimated boss effects are weighted by each observation in the data set, corresponding to the number of worker-days (5,729,508 observations); unweighted, with a fixed effect per boss, but excluding estimated boss effects for those bosses who interact with fewer than ten workers (resulting in 1693 bosses); and unweighted with a fixed effect for each boss for all bosses (1940 bosses).

The estimated standard deviation of the boss effect becomes smaller when focusing on the bosses that have many worker observations in the data. Figures 1 and 2 plot the all estimated boss fixed effects as a function of the number of total observations (worker-days) or the number of workers that the boss interacts with, respectively. Inspection of these figures reveals that for both figures, the dispersion of the estimated boss fixed effects declines as the number of worker-days (Figure 1) or the number of workers (Figure 2) increases.

The results of Figures 1 and 2 correspond to the results in Table 2: as the number of

workers per boss declines (in the three descending rows of weighted boss effects), the standard deviation of the boss fixed effects rises from .39 to .55 to .89. The weighted boss effects using the boss*worker day to gives more weight to bosses who have greater presence in the data.

What causes this? The declining dispersion of the estimated boss effects with the frequency of worker observations per boss could be due to the sorting of bosses in and out of the firm, or due to measurement error in the estimated fixed effects. There is clearly an argument in favor of measurement error: as the number of workers per boss falls, the variance of the estimated boss fixed effects rises, because the extreme values of the boss fixed effects are estimated with very few workers per boss (this is clear in Figures 1 and 2). There is also an argument in favor of sorting; extremely good or bad bosses are more likely to be at the firm for short durations (due to firing or quits), implying that bosses with many worker observations represents a selected sample, but presents a conservative estimate of the variance in boss effects for core permanent bosses.

D. Peer Effects

There is a growing literature on peer effects.¹¹ The basic specification with two-way fixed effects is run while adding a peer effect:

$$(5) \quad q_{ijt} = X_{it}\beta + \alpha_i + \delta_j + \xi p_{ijt} + t + \varepsilon_{ijt}$$

where peer effect, p_{ijt} , is specified in several ways.

¹¹ Most current peer effects papers test whether workers learn from each other due to proximity, or adjust their effort in response to those who work around them (Falk and Ichino, 2006) or who watch them (Mas and Moretti, 2009). Few papers test for the complementarity of skills within the teams that are formed among peers, because skills are unobserved and most data has come from production functions (like store clerks) that are largely individual output, not team output. That is true of this data.

The naïve way to examine whether peers matter is to compute the average output of other workers in the team on a given day and see whether this affects worker productivity. In column 1 of Table 3, the peer effect variable is the average output of the team with which the worker works, excluding own output. The coefficient is .158 which suggests that a one standard deviation increase in a peer’s ability increases own output by .062 units for a worker with average output of about 10 units per hour. This effect of any one peer on a given worker’s output is calculated as

$$\frac{\partial OPH}{\partial Peer Output} = \frac{\partial OPH}{\partial Team Average Output} \frac{\partial Team Average Output}{\partial Peer Output}$$

where the change in the team average output is the change in an individual’s output divided by the team size-1. A one standard deviation change in the quality of a peer is equal to about 3 units of output per hour, so the effect on a worker’s output of working with a peer who is one standard deviation better is (.157) (3) / (9.04-1) = .062.¹²

This is a marked overestimate of the true peer effect. In addition to the standard concerns about the reflection problem (Manski, 20xx), in these data, the calculated peer mean is a excellent proxy for daily demand conditions: if daily demand falls, productivity falls for the team co-workers as it falls for the worker ‘i’ in the regression. Therefore, the estimated peer effect reflects demand variation, rather than the spillover of one worker’s quality on another. The estimated peer effect has a strong upward bias. In these TBS jobs, demand can vary due to fluctuations in transactions from customers, from co-workers who are passing on work, or from

¹² The change in the peer can’t be divided by the team size if you’re using the boss*teamSize because the change in the peer affects all team members

technology mal-functions. The calculated peer team mean does an excellent job of controlling for all of these, and the estimated variance of the boss fixed effects is virtually unchanged (comparing to Table 2 boss effects).

One way to eliminate the temporal reflection problem and the time-based spurious effects is to use peers' fixed effects as measures of the peer output rather than the contemporaneous productivity of other team members. We use a two-step non-linear least squares routine to jointly recover estimates of peer effects, worker effects, and boss effects. The estimating equation for the joint model is

$$(6) \quad q_{ijt} = X_{it}\beta + \alpha_i + \delta_j + \xi \sum_{k \neq i} p_{ikt} + \tau + \beta_{Peer} + \varepsilon_{ijt}$$

where summation over k captures worker i 's team on day t with boss j while excluding worker i . This specification allows the estimated peer effect to depend only on the permanent effect of co-workers on the team, α_k , not on concurrent q_{ijt} . Estimation of the joint model is not feasible on the full set of data because of memory constraints; storage of the matrix of peer-indicators, even in sparse form, requires an order of magnitude more memory than storage of the data with only worker and boss indicators. Because workers and bosses rarely move establishments, the joint procedure can be applied using subsets of establishments. The estimation algorithm is a two-step procedure. The outer-loop "guesses" a value of $\hat{\alpha}_{Peer}$ and then computes the remaining parameters via a linear conjugate gradient procedure in an inner-loop conditioning on the value of $\hat{\alpha}_{Peer}$. Search is then over $\hat{\alpha}_{Peer}$.

The last three columns of Table 3 provide estimates of peer effects, worker effects, and boss effects recovered jointly using the two-step non-linear least squares routine. The regressions in columns 2 and 3 use subsets of the data corresponding to two typical regions,

because joint estimation of worker effects and unconstrained peer effects is only feasible on subsets of the data. The estimated peer effects are zero in column 2 and slightly negative in column 3. The peer effects are not economically significant relative to boss and worker effects.

Another method to estimate peer effects uses a peer's first few months of output as a proxy for the peer's current output. These results are provided in the last column. Again, the coefficient is negative but close to zero.

The conclusion is that peer effects are very small relative to boss effects.¹³ Note that this production environment has relatively little teamwork because each worker primarily interacts with a customer, not with other workers.¹⁴ While the workers can see each other and may learn from each other or compete with each other, the workers do not appear to be complements in production.

IV. Why Do Bosses Matter: Teaching and Motivating

How much do workers learn, and how much do bosses matter for this learning? These questions are addressed by empirically examining the learning curve for workers and then examining the impact of bosses on learning.

In this firm, and in many other technology-based service jobs, workers are required to have product knowledge, and the products are constantly changing. Consequently, it would seem that learning would be an important component of the job. The issue is not whether

¹³ There is also possible sorting of workers into teams of correlated peers, because good workers will work together if given the choice of their preferred shift and there are similar preferred shifts for all workers. If this sorting is temporal, based on recent performance (as it is), introducing worker fixed effects for peer effects will reduce the bias. If the sorting is based on permanent performance, there will be an upward bias in the estimated peer effects. Given that the peer effects are zero or negative, this is not a concern.

¹⁴ The same is true in Mas and Moretti (2009), who also find significant, but small peer effects.

learning is important, but rather whether the variation that we see across bosses reflects difference in their teaching ability, or in something else that we refer to as motivational skills.

A. Learning and Effort by Workers

Workers learn substantially in their first months on the job. As shown in Figure 3, productivity grows by about 2 units in the first couple of months. The learning curve is specified in estimating the output equation with a polynomial in tenure. For these jobs, a portion of the learning is firm-specific and a portion is occupation-specific, and the regressions do not hold constant the latter because the data contains only the start date with the current firm, not general occupational experience. Therefore, the tenure coefficients combine firm-specific learning with occupational learning for those who did not arrive with previous occupational experience, but estimate firm-specific learning for those who arrived with previous experience.

For this type of job, there is negative self selection in exit: the best new hires are more likely to leave the firm than the worst new hires. Comparing the estimated tenure profile with fixed effects (Figure 3) to that from OLS shows the fixed effects profile to be steeper than the OLS profile. Some of the best new hires leave the firm.

B. Teaching and Motivating by Bosses

What drives the dispersion in boss effects? The most obvious factors, especially in the context studied, are teaching and motivating. The model suggests two different skills:

$$(7) \quad q_{ijt} = X_{it} + \alpha_i + \gamma^T Q_j^T + \gamma^M Q_j^M + \beta X_{it} + \varepsilon_{ijt}$$

where Q_j^T is the quality of boss 'j' at teaching and Q_j^M is the quality of boss 'j' at motivating.

Equation (3) assumed boss quality was one-dimensional; here it is two.

How much of the increase in output from bosses is a result of passing on skills and know-how to workers ($\gamma^T Q_j^T$) and how much is simply a result of creating a work setting where workers want to do the right thing ($\gamma^M Q_j^M$)? These variables are unobserved; instead (7) is estimated as (3) except that that $\delta_j \equiv \gamma^T Q_j^T + \gamma^M Q_j^M$.

Some effects of bosses are persistent and some are temporary. When a worker switches bosses, some of the productivity increase that comes from having been with Q_j^M the previous boss remains and some does not. One might argue that skills that are learned are likely to be retained, at least for a period of time, but so too could attitudes that were imbedded in a worker after having served under a particular boss. It is possible that large negative changes in productivity associated with moving from one boss to another might be argued to be more likely to reflect adverse motivation effects of the new boss than skills lost.

The approach here allows a rank-ordering to be predicted of movements from one type of boss to another to be predicted. The relative sizes of the effects are intuitive, but the following specification makes clear what needs to be assumed. Further, it allows for enough specificity to discuss exact identification of teaching and motivation parameters.

Define G_{ijt} as 1 if boss j with whom worker i is paired in period t is a good boss and zero if not. Normalize the effect of teaching on worker productivity to be 1 and the effect of motivation on worker productivity to be μ . Let teaching depreciate such that β_T remains after one period and motivation depreciates such that $\mu\beta_M$ remains after one period. Let us modify (7) to accommodate the two period, two boss type structure. In period 0, where only contemporaneous effects matter,

$$(7') \quad q_{ij0} = X_{i0} + \alpha_i + \delta^* [G_{ij0} + \mu G_{ij0}] + \varepsilon_{ij0}$$

where δ^* is the normalizing parameter such that $\delta^*(1 + \mu)$ is the difference between the fixed effect of the good boss and bad boss. If the bad boss fixed effect is normalized to be zero, then $\delta^*(1 + \mu)$ is just the good boss fixed effect.

In period 1,

$$(7'') \quad q_{ij1} = X_{i1} + \alpha_i + \delta^* [G_{ij1} + \beta_T G_{ij0} + \mu G_{ij1} + \beta_M \mu G_{ij0}] + \varepsilon_{ij1}$$

Output in period 1 can benefit from having a good boss in period 1 both through teaching and motivation, but also can benefit from having a good boss in period zero from a good boss in period zero to the extent that it does not depreciate in moving from 0 to 1.

Using (7') and (7'') and assuming that $X_{i1} = X_{i0}$, write

$$(8) \quad q_{ij1} - q_{ij0} = \delta^* [G_{ij1}(1+\mu) + G_{ij0} (\beta_T - 1 + (\beta_M - 1)\mu)]$$

The following table lays out all of the two period possibilities based on (8).

Table A

Boss Type in two periods	Difference in Boss Effects
Good then Good	$\delta^*(\beta_T + \beta_M \mu)$
Bad then Good	$\delta^*(1 + \mu)$
Good then Bad	$\delta^*[(\beta_T - 1) + (\beta_M - 1)\mu]$
Bad then Bad	0

The analysis provides clear predictions of rank order of the various cells.¹ In order of lowest to highest, the states are Good then Bad (the only negative value), Bad then Bad (equal to zero), Good then Good, Bad then Good (because β_T and β_M are less than 1).

The results in Table 4, which provides the estimates to test predictions in table A, are derived as follows. First, the sample is restricted to those worker-days within a thirty day window of the first boss change. Therefore, these empirical tests are restricted to workers hired after the sample period has begun. Interviews with management at the company revealed that the first boss assignment is nearly random because workers are staffed on teams with vacancies when they exit training. This means there is variation in the quality of a worker's first boss that is not closely related to the worker's own productivity. Second, to avoid having workers with large or small gains between the first few jobs influence the estimates of the boss effects, a separate sample of workers who have had 2 or more bosses is created. Using only the experienced workers, equation (3) is re-estimated to recover boss fixed effects. Combining the boss effects from the experienced sample with the workers in the inexperienced sample allows an examination of the persistence of bosses. Good bosses are defined to have fixed effects above the median and bad bosses have fixed effects below the median.

¹Of course, teaching and motivation are merely names that correspond to the effects that are defined based on μ and the relative depreciation factors. There is no way to tell whether one truly corresponds to teaching and the other to motivation without making an assumption either about the relative contemporaneous importance of the effects or the relative depreciation rate. If we were willing to assume that teaching depreciated more slowly, then we would define the teaching effect as corresponding to the β with that was highest. If this were β_T , it would imply that the effect of teaching on worker productivity was δ^* and that of motivating was $\delta^*\mu$. The alternative is to assume that the larger effect belongs to teaching. Then, if μ is less than 1, the teaching effect is the one labeled with T and β_T corresponds to it.

This creates 4 possibilities: a worker begins with a bad boss and transition to a good boss (20.2% of the sample), begins with a good boss and transitions to a bad boss (18.2% of the sample), begins with a good boss and transitions to another good boss (27.5% of the sample), or begins with a bad boss and transitions to another bad boss (34.1% of the sample). The relevant results related to the rank ordering above are in the second to last column; these results come from a regression of productivity changes on the type of boss transition.

Table A implies three equations in four unknowns and underidentifies the parameters. It is possible to identify the actual parameters by taking advantage of the distinction between senior and junior workers. Assume that all depreciation of boss effects occur within one period (with no further depreciation thereafter).² Also, allow the learning and motivation effects on senior workers to be different than that for junior workers. Specifically, if the learning effect from a good boss on a junior worker is equal to 1 (as above), let the effect for a senior worker be given by ρ_T . Similarly, if the motivation effect from a good boss on a junior worker is μ , then let the effect for a senior worker be given by $\rho_M \mu$. Then (7'), (7'') and (8) become

$$(9') \quad q_{ij0} = X_{i0} + \alpha_i + \delta^* [\rho_T G_{ij0} + \mu \rho_M G_{ij0}] + \varepsilon_{ij0}$$

and

$$(9'') \quad q_{ij1} = X_{i1} + \alpha_i + \delta^* [\rho_T G_{ij1} + \beta_T \rho_T G_{ij0} + \rho_M \mu G_{ij1} + \beta_M \rho_M \mu G_{ij0}] + \varepsilon_{ij1}$$

The difference is

$$(10) \quad q_{ij1} - q_{ij0} = \delta^* \{ G_{ij1} (\rho_T + \rho_M \mu) + G_{ij0} [\rho_T (\beta_T - 1) + \rho_M \mu (\beta_M - 1)] \}$$

²Empirically, the depreciation of boss effects found earlier occur rapidly, with 86% occurring during the first year, which means there is not much left to depreciate thereafter.

As before, (10) can be used to create the analog of table A, but this time for senior workers. That is shown below in table B.

Table B
For Senior Workers

Boss Type in two periods	Difference in Boss Effects
Good then Good	$\delta^*(\rho_T \beta_T + \rho_M \beta_M \mu)$
Bad then Good	$\delta^*(\rho_T + \rho_M \mu)$
Good then Bad	$\delta^*[\rho_T (\beta_T - 1) + \rho_M (\beta_M - 1) \mu]$
Bad then Bad	0

Table B adds three more independent numbers that can be calculated using the data on workers who are already experienced at the beginning of the sample period. Estimation of table A with junior workers and table B with senior workers provides six numbers, thus, six equations in six unknowns: δ^* , ρ_T , ρ_M , β_T , β_M , and μ . All are identified. The estimation is left to a later draft.

C. Two Measures of Output: Productivity and Uptime

Table 5 provides results comparing output-per-hour and uptime. First note that the range of boss effects is larger, both in absolute and percentage terms, on output-per-hour than on uptime. The standard deviation of boss effects is 3.53 for output-per-hour and 0.05 for uptime. This is in part a function of the fact that output per hour varies much more than uptime. The unconditional standard deviation of output per hour is 30.7% of the mean whereas the standard deviation of uptime is 2.8% of the mean. There is a limitation to how important bosses can be in motivating. But that is exactly the point. For service jobs of this type, where monitoring is

easily performed by the information technology, the incremental effect on output of human monitoring or motivation is low. As a result, the variance in that effect is also low.

Most of the action then comes through changing the output per unit of worked time. Little of this is likely to be due to human motivating, again because IT tracks worker output in terms of quantity and even quality because customers are surveyed on their experience. At least in the context of this type of service job, the supervisor's role appears to be one of coach, passing along information and tips on how to accomplish the work more efficiently.

Good bosses, however, appear good along both dimensions. The correlation between the boss effect on output-per-hour and the boss effect on uptime can be computed. The simple correlation of the two fixed effects (bosses on uptime and bosses on output-per-hour) is .12, which is significant at standard levels. Bosses who are better at increasing output-per-hour are better at increasing uptime in their workers as well.¹⁵

Comparing the productivity effects of improvements in uptime versus output-per-hour is straightforward. A standard deviation change in boss uptime quality increases composite output for the average worker by $10.26*(.96+.006) - 10.26*(.96) = .06$ whereas a standard deviation change in output-per-hour quality increases composite output by $(10.26+.39)*(.96) - (10.26)*(.96) = .37$.

V. Robustness

The dataset is large. Therefore, it is possible to split the sample randomly into two separate groups partitioned by worker identifier to examine the extent of sampling error on the

¹⁵ Worker fixed effects are already held constant so this is not a result of good workers sorting to good bosses.

estimated boss effects. After splitting the sample, Sample A contains 2,862,270 person-days and Sample B contains 2,867,238 person-days.

Equation (4) is re-estimated separately for Sample A and Sample B. The correlation between the boss fixed effects in Sample A and Sample B is .37 (N=1854 for bosses in the same connected group in both Sample A and Sample B). Regressing the estimated boss effects on each other, $\hat{\beta}_j = \hat{\beta}_j$ for every boss j in the same connected group across samples, yields an estimated β coefficient of .37 with an R-squared of .14.

As the sample size falls when we split the data set in half, this introduces more noise in the estimation of the boss fixed effects: each estimated boss effect has, on average, half the number of worker switches. This additional noise in the estimated boss fixed effects can account for the estimated β that is less than one in the above regression. Therefore, the next step is limiting the samples to those bosses in both Sample A and Sample B who have at least three workers in each sample may reduce the influence of noise. This restriction reduces the total number of bosses that overlap in samples A and B from 1854 bosses to 1002 bosses. The regression results improve: the estimated β is now .45, thus moving towards one.

The importance of this analysis is that it provides a benchmark for what one would expect when one regresses a boss fixed effect defined in one way on the same boss fixed effect defined in another. There are two reasons for the coefficient to be less than one. First, substantively the fixed effects are unrelated. Second, the fixed effects are estimated with error and errors-in-variables pushes the coefficient toward zero. The A, B sample approach above says that even when the coefficient should be 1 because of the random design for the subsamples, it is only .37, so all future regressions of one kind of fixed effect on another should

be interpreted as deviations from some lower number, like .37, not 1.

VI. Heterogeneity in Boss Effects and in Worker Assignment to Bosses

The effect of bosses on a worker's productivity is likely to depend on the quality of the worker. Good bosses, especially those with teaching skills, may be most useful for those workers who have the most to learn (new workers who begin with low output). Alternatively, the ability of good teachers to raise the output of the best workers may be greater than that for low quality workers. The data provide ways to compare the quality of workers, which permits contrasting, for example, newly hired workers with experienced workers and star new hires with laggard new hires. Stars differ from laggards and old from new workers in a variety of ways that might suggest boss effects are different on the various groups.

Do the subgroups differ? Table 6 contains the summary statistics for group breakdowns. Old workers and stars have higher mean productivity than new workers and laggards. Old workers have more variation in output than new workers, and old workers have a slightly larger coefficient of variation than new workers (.32 compared to .29). Other interesting differences come from comparing stars and laggards. Stars have higher variance in output than laggards, but the coefficient of variation is nearly identical for both groups (around .28).¹⁶

The next sections perform comparisons of estimated boss effects by group to determine for which groups bosses have the largest effects. The logic is as follows. If the boss effect is

¹⁶ Stars also appear more likely to leave than laggards: for the new hires sample, the mean maximum observed tenure for stars 664 days, compared to 820 days for laggards. But the distribution of maximum tenure is wider for laggards: while laggards are more likely to stay longer than stars, laggards are also likely to leave faster (perhaps due to firing).

different for two groups, say, young and old, let N_{it} be a dummy equal to 1 when individual i is young in period t , then

$$(11) \quad q_{ijt} = \alpha_i + \lambda^{\text{New}} N_{it} Q_{ijt} + \lambda^{\text{Old}} (1 - N_{it}) Q_{ijt} + t + \varepsilon_{ijt}$$

where Q_{ijt} is the single dimension of boss j quality, e.g., say, the boss's IQ, for the boss with whom worker i is matched in period t . Then λ^{New} is the transformation of raw boss quality into worker productivity when the worker is a new worker and λ^{Old} is the transformation of raw boss quality into worker productivity when the worker is an old worker.

Boss quality, Q_{ijt} , is unobservable, but boss fixed effects can be estimated for young groups and old groups separately. Thus, write (11) as

$$(12) \quad q_{ijt} = \alpha_i + \delta^{\text{New}}_j N_{it} + \delta^{\text{Old}}_j (1 - N_{it}) + t + \varepsilon_{ijt}$$

where $\delta^{\text{New}}_j = \lambda^{\text{New}} Q_{ijt}$ and $\delta^{\text{Old}}_j = \lambda^{\text{Old}} Q_{ijt}$ and estimate (12).

Will the boss effects, δ^{New}_j and δ^{Old}_j , be bigger for new or old workers (or star or laggard workers)? Theory provides guidance to examine differences in the new and old (as well as star and laggard) treatment effects. Recall that the effect of boss quality on worker output is

$$\frac{\partial q}{\partial S_i} = E \frac{\partial H}{\partial S_i} + H \frac{\partial E}{\partial S_i} \quad i = t, m$$

from equation 2. Good bosses, especially those with good teaching skills, may be most useful for those workers with low stocks of H because $(\partial H / \partial S_T)^{\text{New}} > (\partial H / \partial S_T)^{\text{Old}}$ and $(\partial H / \partial S_T)^{\text{Laggard}} > (\partial H / \partial S_T)^{\text{Star}}$ as predicted by most theories of human capital accumulation or learning by doing.

A complication, though, is that each term is multiplied by the corresponding amount of effort or

stock of human capital. Therefore, it is conceivable that better teaching bosses should be paired with star workers, not because stars have more to learn, but because each change in the quality of human capital is applied to a larger stock of human capital for stars. Similarly, if old workers worked harder than young workers (unlikely), it would be possible that the optimal pairing would have the best bosses with the old, not the young. Theory provides insights on why the effects may differ; data are needed to estimate the magnitudes of the offsetting effects.

A. Does Non-random assignment of workers to bosses bias the estimated boss effects?

There is not a random assignment rule; there would not be in any workplace. But it is often the case that actual assignment is nearly random, because worker turnover rates are high. High quality workers could be paired with high quality bosses because older workers and older bosses get their preferred work shifts. It is equally possible that there is no sorting bias, because many new workers and new bosses are higher quality than old workers and bosses. Recall that the highest quality workers are more likely to leave the firm than the lowest quality. However, a formal analysis of these assignment biases is required.

Stated more generally, to estimate this average boss quality treatment effect on worker productivity, either there is random sorting between bosses and workers after accounting for the worker's fixed effect and X , or the boss treatment effects must be homogeneous across workers. As stated in section III.C above, this means $\delta_j = E(y \mid \text{Boss } j, \text{ worker } i) - E(y \mid \text{Boss } 1, \text{ worker } i) = E(y \mid \text{Boss } j, \text{ worker } k) - E(y \mid \text{Boss } 1, \text{ worker } k)$ for all workers i and k . We aim to let the treatment effects be heterogeneous across subgroups, so random assignment is needed to estimate unbiased treatment effects. To capture this, rewrite (11) as

$$(11') \quad q_{ijt} = \alpha_i + \lambda^{\text{New}} N_{it} Q_{ijt}^{\text{New}} + \lambda^{\text{Old}} (1 - N_{it}) Q_{ijt}^{\text{Old}} + t + \varepsilon_{ijt}$$

where the subgroups sort to different quality bosses, and quality differences enter the estimation of (12). Alternatively, if every boss has at least some workers assigned to him in the new and old subgroups, then the estimated heterogeneous boss effects are unbiased—equation (11) prevails. Thus, even if boss ‘j’ has only 5 new workers and 25 old workers, his estimated boss effects by group will be unbiased, though the precision of the estimated effect for boss ‘j’ is lower for new workers given only 5 observations per boss. Therefore, the analysis of bias henceforth is an analysis of whether there are bosses excluded from one group or the other.

Using new and old workers as the comparison groups, the estimated distribution of boss effects is biased when the *excluded* group of bosses, namely those bosses who had either only new or only old workers, is different in their effects on worker productivity from the *included* group of bosses who had both new and old workers. If the assignment of workers to bosses is not random, then there is the potential that the effects of bosses on the two groups (new and old) is only relevant for those *included* bosses who have had both.

Is the proportion of bosses having both new and old workers relevant to this calculation of potential bias? Yes, but even were the proportion of omitted bosses small, it is still possible that the excluded bosses could still be fundamentally different from the included bosses. It means, however, that we probably care less about the excluded group than the included group because it is a small part of the population. Put differently, the population distribution of boss effects, which is the weighted average of the included and excluded bosses’ fixed effects, is

likely to be close to the included group estimates alone when the included group is a large proportion of the total population.¹⁷

Let us examine the potential bias formally. The population parameter of interest is

$$\sigma^{\text{New}} = (\#\text{Bosses}-1)^{-1} * (\sum_{j \text{ with new}}(\delta_j - \delta)^2 + \sum_{j \text{ without new}}(\delta_j - \delta)^2)$$

where δ is the mean. Here $\sum_{j \text{ without new}}(\delta_j - \delta)^2$ is censored, and this omitted term is the source of bias (another source of bias may come from incorrectly estimating δ , the population mean).

Notice that because of the summation, the weight on the term from the uncensored sample, $\sum_{j \text{ with new}}(\delta_j - \delta)^2$, is the number of bosses with new workers over the total number of bosses. As the number of bosses with new workers relative to the total number of bosses increases, the estimated parameter approaches the population parameter.

There is a second issue. The analysis above focuses on whether the overall distribution of treatment effects is biased. However, much of the analysis of heterogeneity in estimated treatment effects uses the boss effects for only the included bosses, who have both new and old workers on their teams. For the set of bosses who work with both old and new workers, the regression $\delta^{\text{New}}_j = a + b \delta^{\text{Old}}_j$ is estimated, because it assesses whether a good boss is always a good boss for new and old workers.¹⁸ But the regression is feasible only for the included group.

¹⁷ For this not to be the case, the parameter in the excluded group would have to be very different from that in the included group.

¹⁸ The only way to compare the magnitude of boss j 's effect on new workers with boss j 's effect on old workers is if boss j works with new and old workers in the same connected group. Suppose a boss works with new and old workers in different connected groups; that is, boss k interacts with new workers in connected group 1 and boss k interacts with old workers in connected group 2. Then it is not possible to compare the magnitude of boss k 's effect on new workers with boss k 's effect on old workers because boss k 's effect on new workers is $\delta_k = E(y \mid \text{boss } k, \text{ new workers in group 1}) - E(y \mid \text{boss } 1, \text{ new workers in group 1})$ whereas boss k 's effect on old workers is $\delta_k = E(y \mid \text{boss } k, \text{ old workers in group 2}) - E(y \mid \text{some boss } \neq 1, \text{ old workers in group 2})$.

If the excluded group is large, then there is sample selection bias introduced into the calculated correlation.

How big are the excluded groups in these data? Here is the breakdown.

New and Old Workers

Excluded Bosses	Excluded Bosses	Included Bosses	Total Bosses
New workers	Old workers	New and old workers	
70	146	1720	1940

Star and Laggard Newly Hired Workers

Excluded Bosses	Excluded Bosses	Included Bosses	Total Bosses
Laggard workers	Star workers	Laggard and star	(for new hires)
134	181	1711	1854

group 2). Notice that boss 1 is the excluded boss in connected group 1, but there is a different excluded boss in connected group 2.

Thus, for the two alternative breakdowns, new/old and laggard/star, the proportion of the population that is excluded is very small: the included are 89 percent and 92 percent, respectively.¹⁹

This is suggestive that most worker assignment to bosses is close to random, and assignment bias is minor. No general statement can be made that there is no assignment bias for all possible partitioning of the data into subgroups. For example, if the assignment were to four different subgroups, rather than two, the possible bias could rise, and the proportion included falls. But this is unlikely; the groups above are the most likely breakdowns as described by the firm.

B. Boss Effects for New and Old Workers

The distribution of boss effects for old and new workers is given in the first column of Table 7. The standard deviation of boss effects for new workers (weighted by the boss's total frequency with new workers) is .39 compared to .44 for old workers (weighted by the boss's total frequency with old workers). Bosses are slightly more important for old workers from this analysis. The difference between a good boss and a bad boss seems to have a larger effect on older workers than on younger ones, but only slightly so.

For the set of bosses who work with both old and new workers, the correlation in a boss's effect for old and new workers can be estimated.²⁰ The correlation in boss effects for old

¹⁹ For bosses who work with stars, star workers' mean (standard deviation) [Number of observations] daily output while matched with a boss who never works with laggards is 11.5 (3.97) [2922], whereas output for star workers while matched with a boss who works with both stars and laggards is 11.2 (3.1) [1713567]. Similarly, laggard workers' output while matched with a boss who never works with stars is 8.78 (3.0) [7073], whereas output for laggard workers while matched with a boss who works with both stars and laggards is 9.56 (2.67) [2005916].

and new workers is positive and significant (0.36), suggesting that bosses who are good for new workers are also good for old workers. Note also that this correlation is almost identical to the simple A, B random group correlation of boss effects, which attempted to show what the effect would be were there mere errors in variables and were the true coefficient one. In this case, that would imply that b would equal 1 in

$$\delta^{\text{New}}_j = a + b \delta^{\text{Old}}_j$$

but the estimated coefficient would be .37 from the A, B comparison as long as the noise in the old/new comparison associated with estimate the boss effects was the same as that in the A,B comparisons above. This correlation is estimated within the largest connected group; 99.99 percent of the sample falls within the largest group. The inference is that a one dimensional view of boss quality is a good description of what is going on for new and old workers.

Were the true coefficient, absent the errors-in-variable bias, one, there would be no clear advantage to pairing good bosses with new or old workers. Were the true coefficient greater than one, the best bosses should be paired with new workers. Were it less than one, best bosses should be paired with the old workers. The fact that the variance in boss effects for old and new

²⁰ The only way to compare the magnitude of boss j's effect on new workers with boss j's effect on old workers is if boss j works with new and old workers in the same connected group. Suppose a boss works with new and old workers in different connected groups; that is, boss k interacts with new workers in connected group 1 and boss k interacts with old workers in connected group 2. Then it is not possible to compare the magnitude of boss k's effect on new workers with boss k's effect on old workers because boss k's effect on new workers is $\delta_k = E(y | \text{boss } k, \text{ new workers in group 1}) - E(y | \text{boss } 1, \text{ new workers in group 1})$ whereas boss k's effect on old workers is $\delta_k = E(y | \text{boss } k, \text{ old workers in group 2}) - E(y | \text{some boss } \neq 1, \text{ old workers in group 2})$. Notice that boss 1 is the excluded boss in connected group 1, but there is a different excluded boss in connected group 2.

workers is about the same is consistent with the true coefficient, corrected for errors-in-variable bias, being close to one.

C. Boss Effects for Stars and Laggards

The second column of Table 7 provides the results for boss effects for stars and laggards. The weighted standard deviation of the boss effects for stars is 0.61 and for laggards is 0.39. Whether the estimated standard deviation of boss effects reflects the population standard deviation of boss effects requires some care; some bosses only work with stars and some bosses only work with laggards. Recall from above that there are 1,806 bosses who ever work with laggards, 1,759 bosses who ever work with stars, and there are 1,711 bosses who work with both stars and laggards. The within boss correlation of boss effects for stars and laggards (for bosses with both stars and laggards in the largest connected group) is .20.

Again, the approach of regressing

$$\delta^{\text{Star}}_j = a + b \delta^{\text{Laggard}}_j$$

could be used to determine whether bosses are similar. The correlation of .20 from Table 7 suggests that those who are good for stars are also good for laggards, but that the relationship is not perfect. The regression of estimated δ^{Star} on δ^{Laggard} produces an estimated coefficient on δ^{Laggard} of .44, with a constant of .31. The fact that .44 is less than one would, if it were bias-free, imply that the good bosses should be assigned to laggards rather than stars. Two facts alter this conclusion. First, the reverse regression of laggard fixed effects on star fixed effects yields an even lower coefficient. Second, the fact that .44 exceeds the .37 in the A,B comparison discussed above suggests that the true coefficient is likely greater than 1. Coupled with the fact that the variation in boss effects is substantially greater when bosses are matched with star

workers than when they are matched with laggard workers, the conclusion is that bosses affect the output of stars by more than they do laggards.

These results suggest that good bosses should be paired with the best workers. However, a “good boss” for one type of worker is not necessarily a good boss with another type of worker. Because the boss effects are not perfectly correlated for new and old workers or stars and laggards, there is room for assignment based on comparative advantage. The findings suggest that those bosses who are best at raising the productivity of new workers or laggards should be assigned to new workers or laggards, provided those bosses are not much better at raising the productivity of the complement group.

As an operational matter, a boss’s quality, i.e., the boss’s group specific fixed effect, can be determined at the level of a firm by using the approach above. It is then possible to decide to which boss a laggard should be assigned and to which a star should be assigned. This can be done by the firm to make more efficient assignments of workers to supervisors.

VII. The Marginal Product of Bosses

Because the number of team members per boss varies, it is possible to identify the effect of additional boss time on worker productivity. This, in essence, estimates the marginal product of boss time, or at least that component that works through enhanced worker productivity. The obvious problem is endogeneity. Better bosses may be assigned to supervise more workers, which would bias downward the observed effect of adding boss time on worker output. Additionally, the average tenure in the firm rose between 2006 and 2010, which would also affect productivity, but in the opposite direction were other things the same.

The firms’ training policy provides an approach to dealing with potential endogeneity.

When a worker leaves the firm, vacancies are filled by new workers. However, there is often a lag between a worker leaving and the availability of a replacement worker. Each new worker spends several weeks in training with other new workers, and vacancies are filled when a full training cohort is available upon the end of a training cycle.

Consequently, an instrumental variables approach is used. The key potentially endogenous variable is workers-per-boss (the team size). The first stage regression is

$$(10) \quad \text{teamSize}_{ijt} = \alpha_i + \delta_j + \text{trainingCycle} \delta_1 + \text{trainingCycle}^2 \delta_2 + f(\text{tenure}_{it}) \delta_3 + t + \varepsilon_{ijt}$$

where team size is a function of the number of days since the last training class ended at each establishment. Monthly time dummies are used to control for a decrease in turnover and hiring during the recession. Column 1 of Table 8 provides details about the first stage. The residual sum of squares from regressing team size on a tenure polynomial, month dummies, worker fixed effects and boss fixed effects is 35,433,666 compared to a residual sum of squares of 35,276,835 when including a quadratic function of the number of elapsed days since the last training cohort entered the establishment. This yields a first stage partial F on the instruments of 12,678. The overall F statistic on the first stage is 106.

The estimates in the first stage imply that team size is .13 workers smaller after 19 days into the training cycle (the mean training cycle lag observed in the data) versus at the beginning. A one standard deviation increase in the training cycle, to a 52 day lag, decreases team size by an additional $-.35 - .13 = .22$ workers. A one standard deviation change in the training cycle thus provides a roughly 4% change in team size.

The regression of interest is

$$(11) \quad q_{ijt} = \alpha_i + \delta_j + \beta_1 + f(\text{tenure}_{it})\beta_2 + t + \varepsilon_{ijt}$$

where output-per-hour is regressed on team size, with controls for tenure, monthly time dummies, worker fixed effects, and boss fixed effects. The results are reported in Table 3 in the remaining columns.

From these numbers, it appears that reducing team size significantly increases each worker's output-per-hour. This is true in both OLS and IV versions. The coefficient is interpreted as the effect of adding one worker per boss on individual output. This implies that adding another worker to a team increases total output less than the impact of the additional worker's productivity. The coefficient on team size in the IV regression is greater than the OLS coefficient, consistent with the view that better bosses are assigned a larger number of workers, which would bias down the effect in OLS.²¹

Using the IV estimates, total output is given by $N*(oph - 0.187*N/B)$ where N is the number of workers in the company and B is the number of bosses. Therefore, the marginal product of a boss is $0.187N^2 / B^2$. On a typical day, the marginal product of an additional boss is approximately 15.5 units of output. The marginal product of a worker can be calculated as $oph - 0.374N / B$. The marginal product of an additional worker is about 6.9 units of output. In terms of a boss's effect on output as it operates by increasing worker productivity, a boss is twice as important as a worker. There may be things that a boss does as well that are not captured by the

²¹ The IV estimates of the effect of team size are obtained using the projection from the first stage as a regressor in the second stage. Standard errors cannot be computed because of difficulty in inverting the matrix of regressors, but a comparison of the residual sum of squares with the model excluding team size and the corresponding F-test confirm that team size is statistically significantly related to output.

effect through workers alone, but these numbers are consistent with levels of compensation received by bosses and workers as well, where a boss could earn approximately twice as much as a typical worker.²²

VIII. Conclusion

Supervision and management are a fundamental concept in personnel economics and in the theory of the firm. Although we take as given that managers matter, neither the mechanisms through which they affect productivity nor the actual size of the effects has been spelled out previously. By using a unique data set that gives very detailed daily output on workers and records the supervisors to which they are assigned on that day, it is possible to examine the effects of bosses on worker productivity.

Boss effects are large and significant. The value of a boss is about twice that of a worker. Further, bosses vary substantially. A very good boss increases the output of the supervised team over that supervised by a very bad boss by about as much as adding one member to the team. Additionally, peer effects are trivial. The only “peer” who matters in this work environment is the boss. Finally, good bosses increase the output of the better workers by more than they do for the poorer workers. Consequently, the assignment of supervisors to workers matters; productivity can be increased by sorting bosses appropriately to workers.

²² The company did not supply compensation data, but in conversations with managers about levels of compensation, a ratio of 2:1 boss-to-worker compensation is not out of line.

Number of Unique Workers Per Boss	1,940	49.15	35.41	1.0	250.0
Mean Number of Other Bosses for Each Worker	1,940	4.69	1.51	0.0	11.3

Notes:

The data contain daily worker productivity records from June 2006 to May 2010. Output per hour is calculated from records that contain the average daily transaction handling time for each worker. Uptime is calculated from an IT system that monitors the fraction of clock time that a worker is available to handle transactions. There is some missing data on uptime. The missing uptime data is concentrated toward the beginning of the sample period. The mean of output per hour when restricting the sample to the 4,870,610 worker-days with non-missing uptime is 10.38 with standard deviation 3.08. Eliminating daily teams with 1 person removes 80,067 person-days and changes the mean daily team size to 10.20.

Table 2: Regressions of Output-per-hour on combinations of fixed effects

Number of bosses	1,940	1,940	1,940	1,940
Percent of sample in largest connected group				99.99

Notes:

All specifications contain a fifth order polynomial function of tenure and monthly time dummies. Worker fixed effects are mean zero, and one boss fixed effect is restricted to be zero. Fixed effects weighted by the number of observations correspond to the sample frequency of observing those fixed effects, whereas unweighted or "1 per-person" measures perform calculations using individuals (either bosses or workers) as the unit of observation. Because boss effects are not estimated precisely if the boss has very few observations, the unweighted boss effects after excluding some bosses measures drop bosses who oversee fewer than 10 workers or who have fewer than 87 worker*boss days in the data. This exclusion leaves 1693 bosses.

The boss fixed effects are not adjusted for team size. The boss fixed effects weighted by the number of observations implicitly give bosses with larger teams and longer tenure more weight. The boss and worker fixed effects in the 1 per-person category compute standard deviations over the estimated fixed effects (not over observations).

Table 3: The Effect of Peer Quality on Output-per-hour

Estimation method:	OLS	Joint NLS	Joint NLS	Peer Proxies
R-Squared	0.2475	0.2356	0.3778	0.2421
Coefficient on Mean Team Output or Implied Output	0.158	0.001	-0.015	-0.028
Implied Standard Deviation of Peer Effects	0.062	0.022	0.006	0.01

Number of Workers	23,878	1679	1814	23,878
Number of Bosses	1,940	155	124	1,940
Number of Observations	5,729,508	391,730	424,233	5,729,508

Notes:

All specifications contain a 4th order polynomial in tenure, month, boss, and worker fixed effects. Standard errors cannot be computed. The first column contains the mean contemporaneous output for all other team members on a given day. Joint estimation columns estimate use non-linear least squares, using the average of the team members' individual fixed effects as a measure of peer quality. The joint estimation procedure is computationally demanding; an "outer" loop is used to search over the peer effect coefficient, while an inner loop conditions on the outer loop value and solves for the parameters using a conjugant gradient procedure. The joint procedure is not possible on the full data because of memory issues in Matlab; storage of the matrix of peer fixed effects requires an order of magnitude more memory than using a single-dimensional index of peer quality. The peer proxies uses mean output on the first three months on the job as the value of peer quality. If a worker's first three months are not observed, then the mean value of all observed workers' first three months is used.

F statistic	21.7***	127.2***
F on Joint Fixed Effects	53.3***	20.7***
Number of Observations	5,729,508	4,870,610
Number of Bosses	1,940	1,726
Percent of sample in largest connected group	99.99	99.99
Correlation of Worker Oph and Uptime Fixed Effects	-0.26	
R-squared from regressing Worker Oph Effects on Uptime Effects	0.071	
Correlation of Boss Oph and Uptime Fixed Effects	0.12	
R-squared from regressing Boss Oph Effects on Uptime Effects	0.021	

Notes:

All specifications contain a fourth order polynomial function of tenure and monthly time dummies. Worker fixed effects are mean zero, and one boss fixed effect is restricted to be zero within each connected group. Some data on uptime is missing toward the beginning of the sample period.

Table 6: Summary Statistics for Heterogeneous Worker Groups

Variable	Obs	Mean	Std. Dev.	Min	Max

For Laggard Workers (Weighted by frequency with laggard workers)		0.39
For Laggard Workers (1 per-boss)		0.75
P Value of Heterogeneous Boss Effects versus Homogeneous Effects	0	0
Number of Observations	5,729,508	5,729,508
Percentage of Observations in the Largest Connected Group	99.99	97.51
Number of Observations in the Second Largest Connected Group	0.01	2.46 [See Note A]
Number of Bosses with Old Workers (Star Workers)	1,794	1,759
Number of Bosses with New Workers (Laggard Workers)	1,870	1,806
Number of Bosses with Both Worker Types in the Largest Connected Group	1,709	1,532
Correlation of New (Laggard) and Old (Star) Boss Effects	0.36	0.2

Notes:

Standard deviations of boss fixed effects are weighted by the number of observations or number of bosses within each connected group. Correlations of boss effects are restricted to bosses whose new/old and star/laggard effects are estimated within the same connected group. For the new/old specification, 1720 bosses work with both new and old workers, with 1709 bosses having new and old workers within the same connected group. For the star/laggard specification, 1854 bosses work with either stars or laggards; 1711 bosses work with both stars and laggards, with 1532 bosses having both stars and laggards within the same connected group. All specifications contain a fourth order polynomial function of tenure and monthly time dummies. Worker fixed effects are mean zero, and one boss fixed effect is restricted to be zero for each sub-group. In the star/laggard specification all workers are included to estimate the tenure profile and month dummies. Amongst stars and laggards only, the number of observations is 3,729,478.

[A]: The second largest connected group contains all laggard workers and boss*laggard vectors for bosses working with laggards who never work with stars or other laggards who are connected to other bosses. There are 91,658 observations and 170 unique boss*laggard fixed effects in this group; the standard deviation of boss fixed effects for laggards in this group (weighted by frequency) is .64. However, only 7 unique bosses in the group never work with stars. The third largest connected group has only 501 observations and contains only laggards and boss*laggard vectors. The largest group containing only stars and boss*star vectors has 333 observations. There are 26 overall connected groups.

Table 8: The Marginal Product of Bosses

	First Stage OLS Team Size	OLS Output-per-hour	IV
First Stage Results			
Mean elapsed days since last training cohort entered (Training cycle):	19		
Standard deviation:	33
